Highlights

- Information sharing decisions are supported by a value-based decision-making process.
- Neural value signals respond to attributes of media content.
- Neural value signals respond to social influence.
- Neural value signals integrate media and social influences, explaining interaction effects on decisions.
- Neural valuation is context-dependent, affording context-sensitive sharing decisions.
Abstract

Exposure to media content (e.g. persuasive campaigns) affects daily behaviors, but these effects are partially determined by whether and how people who are exposed to the content share it with their peers. To decide whether to share, potential sharers need to compare and integrate diverse sources of information including characteristics of the media content and various social influences. What are the mechanisms that enable sharers to make such complex decisions quickly and effortlessly? We review evidence that sharing is preceded by a value-based decision-making process supported by three key characteristics of the so-called neural valuation system (domain-generality, value integration, and context-dependence). Finally, we describe theoretical and methodological advances that can be gained from conceptualizing sharing as a value-based decision-making process.

Keywords: information sharing, value-based decision-making, neuroscience, social influence, media
1. Introduction

Imagine a college student, Anna, whose friend, Julie, is drinking too much alcohol, too quickly. Sharing information about the risks of binge drinking from a public health media campaign may help Anna convince Julie to stop drinking. Yet, the prevailing social norm among college students tends towards pro-alcohol conversations [1–3] and suggests that Julie may react unkindly if Anna shares the anti-binge drinking information. As this example illustrates, when deciding whether to share media content with others, potential sharers usually integrate at least two types of information, namely information about the media content itself [4,5] (e.g. its credibility, relevance, or usefulness) and about relevant social influence(s), including perceived social norms or opinions expressed by peers, for instance those the content could be shared with [6,7]. For Anna, integrating two such inherently incomparable inputs to decide what information to share is akin to comparing proverbial apples and oranges. Despite this complexity, in daily life, people make sharing decisions relatively effortlessly and share media content without laboriously weighing each pro and con of sharing. What mechanisms make this possible?

Understanding the processes that lead to sharing is important. Sharing media content can profoundly impact attitudes and behaviors in large groups [8–12] by selectively amplifying or changing effects of some, but not other [5,8,9], pieces of media content on target audiences in ways intended or unintended by the original content creators [10–12]. Social- and neuro-sciences have formally modeled increasingly complex types of human decision-making, from simple choices between two options to complex, context-dependent decisions between multiple alternative options, taking into account multiple decision-relevant attributes [16,17]. These models identify key parameters and mechanisms that drive decision-making across contexts and can help to better understand and predict complex real-world decisions about media content sharing. A central concept in this literature is subjective value maximization, a process by which decision-makers choose the option that is perceived to be most valuable given the available information. Here we discuss how key characteristics of value-based decision-making and the underlying neural mechanisms can support real-world sharing decisions.

1 Prominent examples of media content sharing on society are evident across domains like politics and health. For instance, news stories shared on social media played a significant role in recent democratic elections (e.g. [5,13]) and the effectiveness of health-promotion campaigns partially depends on whether and how they are discussed socially [10,14,15].
2. Value-Based Decision-Making and Sharing

In hundreds of neuroimaging studies, the extent to which a stimulus was perceived as valuable by a participant consistently scaled with brain activity within areas of the so-called neural valuation system (Figure 1A, [18–20]), including ventromedial prefrontal cortex (VMPFC) and ventral striatum (VS). Activity in these brain regions in response to a stimulus also predicts subsequent laboratory choices [21,22] and real-world actions like donations [23].

Neural activity in value-related brain regions is also centrally involved in decisions about information sharing [24–26]. Yet, sharing research has yet to take full advantage of insights from basic decision-making research on the parameters and mechanisms driving neural value-related activity. We highlight how three key characteristics of the neural value signal may support sharing decisions (Section 2.1-2.2; Figure 1B) and describe implications of this psychophysiological framework of sharing for future research (Section 2.4).

2.1 Domain-General Value and Value Integration

What might be going on in Anna’s brain as she decides whether sharing information from the anti-drinking campaign with Julie is a valuable option? As illustrated above, she may note, compare, and weight the relevance of the media content itself and anticipated social influences like opinions and potential reactions of peers. At first glance, Anna is comparing apples and oranges. Neuroscientific research, however, suggests that the neural value signal is domain-general, such that it allows the processing of diverse decision inputs within one network of brain regions. Further, neural value-related activity also allows direct comparisons between inherently incomparable inputs using a process called value integration.

Specifically, domain-generality means that the neural valuation system encodes the subjective value of and predicts behavioral responses to a wide range of stimuli including primary, monetary, and social rewards [18,19,27]. That is, decisions as diverse as whether to eat a chocolate bar [28] and whether to donate to a crowdfunding campaign [29] are, in part, supported by overlapping regions of the brain. To this end, a large number of functional connections between the neural valuation system and other brain areas allow the valuation system to collect information from computations that occurred elsewhere in the brain in one set of regions to compute their respective subjective values [30–34].
Domain-generality of the neural value signal extends to decision inputs that are relevant to decisions about sharing such as Anna’s, including the evaluation of attributes of the media content (e.g. Is the source credible?) and social influence (What will my peers think about this information?; for a review see [35,36]). Few studies have directly examined inputs to the neural value responses during sharing decisions (e.g. neural valuation of sharing as a function of media content or social influence; c.f. [24,25,37]). However, work in other domains demonstrates that value-related brain responses to media stimuli like crowdfunding campaigns, New York Times articles, and public health campaigns tracks with people’s preferences for the content and subsequent behaviors within study samples [24,38–40] and out-of-sample behaviors of large populations such as New York State smokers [41] and users of crowdfunding websites [34]. Similarly, effects of social influence on behavior are supported by neural value-related activity. For instance, information about social rewards, like learning that one’s actions conform to group norms [42–46], enhances activity within the neural value system [42,47]. This neural activity then predicts whether or not people conform to social influence [48,49]. In sum, the neural valuation system supports the evaluation of choices based on both media content and social influence and, thus, likely plays a crucial role in sharing decisions (Figure 1B).

Yet, domain-generality in itself does not solve Anna’s problem. Beyond processing media and social inputs to her decision separately, Anna must compare and weigh them against each other to maximize the value of her final choice using all the available information. To support this value integration process, the neural value signal represents diverse information in a comparable manner by translating seemingly incomparable information onto a common scale using a so-called common-currency signal [30,50–52]. To understand this metaphor, imagine you are an American being offered money for a service from two potential international buyers. One offer is in Euros, one in Pounds. Deciding which bid is more valuable, requires an understanding of the exchange rate between the currencies. As American, you are likely to convert both offers into US Dollars, a common currency. The neural value (or common-currency) signal provides such exchange rates, even for seemingly incomparable inputs like media content and social influence. Using the common-currency signal, decision-makers may up- or down-weight the value assigned to features of one type of input (e.g. the quality of arguments in an anti-drinking campaign) depending on features of another influence type (e.g. the attention span of a drunk conversation partner) and thereby integrate them into one coherent
decision. Hence, the common-currency signal enables decision-makers to choose the most valuable option by integrating multiple, diverse inputs.

For sharing decisions, behavioral research has shown that social influences affect the interpretation and perceived importance of media content and vice versa [10]. The role of neural value integration in this context has not been tested directly. Yet, recent evidence suggests that this is a fruitful direction for future work. Specifically, neural value-related activity mediates effects of brain activity within self-related and social processing areas to predict sharing behavior [25], suggesting that the neural valuation system integrates inputs from other regions during sharing decisions. To interpret these findings using Anna’s example: Anna’s neural value signal may allow her to integrate thoughts about potential consequences of sharing the anti-alcohol media campaign for herself (e.g. Will I look knowledgeable or like a ‘know-it-all’?) and for her relationship with Julie (e.g. Will Julie think I’m being annoying or a good friend?). External information like media content and social influence may inform evaluations of whether these internal motivations can be achieved by sharing the anti-drinking campaign. Consistent with this value integration perspective, participants of another study who were more successful at increasing their neural value-related activity while viewing anti-drinking campaigns using an emotion-regulation strategy were also less susceptible to pro-drinking peer influence in the following month [3]. That is, consciously boosting effects of media content on behavior was associated with reduced susceptibility to contradictory social influences. In sum, extant evidence points towards a value integration role of the neural valuation system when decision-makers consider social and media influences. However, this theory has not been tested conclusively in the context of sharing.

2.2 Context-Dependent Valuation of Media and Social Influence

Finally, an additional layer of complexity in sharing decisions is the fact that the same (mediated and social) inputs can have different effects in different contexts. For instance, Anna’s decision about whether to share anti-binge drinking media information with Julie would be affected by how long ago she saw the media campaign and whether it is top of mind (‘temporal context’) and by whether she is alone with Julie or with other drinking/non-drinking peers (‘spatial context’). That is, the value that a piece of information contributes to a decision is not absolute, but relative to relevant and irrelevant contextual information [53,54]. Similar to sharing behavior, the neural value signal is affected by both temporal (information encountered
previously) and spatial context (alternative decision options available at the time of choice [17,55,56]). Specifically, across species, neural value-related activity is partially dependent on the value of alternative options/stimuli [55]. For instance, the neural value assigned to eating an apple increases with the subjective value of apples, but decreases when alternative, highly valuable snack options (e.g. chocolate bars) are available.

In the context of sharing, the size of a sharer’s potential audience impacts the extent to which brain regions, known to be important in sharing decisions, are engaged during decisions about news sharing [7]. Further, while making sharing decisions about news articles, participants who identified as avid news readers showed greater functional connectivity between the neural valuation system and brain areas often associated with deliberate/effortful processing [57]. In sum, extant evidence suggests that a systematic integration of contextual features into future research on value-based decisions about information sharing may help to better understand and predict sharing decisions.

2.3 Theoretical Implications and Future Directions

In sum, extant evidence supports the idea that value-based decision-making in the brain has key characteristics which can support specific requirements of information sharing decisions. Yet, many specific predictions made by formal decision-making models have not yet been tested in the sharing context. One example is the prediction that the neural value signal encodes both social influence and media content in a comparable manner and, thereby, explains interactions between these types of influence on media content sharing. In turn, studying sharing through the lens of value-based decision-making and paying special attention to individual characteristics of neural value-related processing has several theoretical and methodological advantages.

First, the domain-generality of neural valuation suggests that overlapping mechanisms drive previously separate research lines focused on social influence [58] or media content effects on sharing [4]. This calls for a overarching theoretical framework. To further develop this research line, experiments should systematically vary features of media content or social influence to assess causal effects on neural value-related activity and sharing behavior.

Second, the role of the neural valuation system in value integration may explain how seemingly incomparable types of influence like social influence and media content are seamlessly integrated into daily sharing decisions. This can help to explain and forecast real-world situations such as Anna’s in which decision-makers are confronted with conflicting
information from multiple sources. Relatedly, neural valuation as a summary signal of diverse decision inputs is a useful methodological tool when studying mechanisms of decision-making, because lay participants struggle to report complex value integration processes through self-report.

Finally, prior work has studied and theorized information sharing behaviors separately in different domains such as politics, health, and marketing which is inefficient. Understanding and quantifying the context-dependence of the neural value signal during sharing decisions allows for future research to further understand and predict the sharing of media content across contexts (e.g. depending on the time of day).

In sum, sharing can be conceptualized as a value-based decision-making process, and formal tests that derive from this conceptualization stand to advance both theory and practice.

Annotated Bibliography

*Jeong and Bae conducted the first formal meta-analysis examining the extent to which interpersonal conversations about a health campaign mediate campaign effects. On average, campaign-generated interpersonal communication showed a positive effect on campaign-targeted outcomes. This effect was moderated, among others, by the campaign’s topic, the targeted outcome, and the conversation partner with whom individuals talked about the campaign.*

Busemeyer and colleagues provide a recent review of advances in decision-neuroscience, particularly in describing multi-attribute, multi-alternative decisions, which moves the field closer to describing complex real-world decision-making. They describe efforts to model such decisions with increasingly sophisticated models and provide an overview of what is known about the underlying neural mechanisms. The authors highlight the importance of context-dependence in choice behavior as well as initial neuroimaging evidence capturing context effects.

Chawla and Miyapuram provide a helpful overview of research in several decision-making domains including value-based decisions, sensory decisions, and social decision-making. The authors argue that, although these types of decisions have long been studied separately, complex real-life decisions cannot be neatly assigned to only one category, suggesting the need for domain-general frameworks of decision-making. Understanding context-effects on choice behavior including mechanisms such as normalization or neuronal adaptation is identified as an important step towards such a framework.

Falk and Scholz review and integrate literatures in communication science, social psychology, social, and cognitive neuroscience to provide a mechanistic account of persuasion and social influence, including information sharing behaviors. Value-based decision-making and its underlying neural mechanisms are highlighted as central components of a diverse set of persuasion-related processes.

The study described by Klein and colleagues is an excellent example of an empirical neuroimaging study that demonstrates the context-dependence of value-based decision making. The authors show that novel choice contexts lead to choices that are incongruent with previously learned choice algorithms. Instead, the evidence suggests that decision-makers value choice options relative to previously encountered options and that this relative option value is encoded in the neural value system.
